Early exiting position

True: 82 | Pred: 82

... 's 8 2 . Seems small , but maybe correct ? Alternatively ,
think of the number of possibilities for internal edges and external
edges . Earlier , we found that for each internal edge configuration
(a ,b ,c ,d), there are some number of external color ings . And
total over all internal configurations is 8 2 . Therefore , 8 2 is
the answer ? But let me check with another approach . Suppose we
model this as a graph and use linear algebra over GF (2). However
, the constraints are not linear equations but rather exact counts .
However , maybe we can find dependencies . Alternatively , think of
the problem as a constraint satisfaction problem where each square
imposes that the sum of its edges is 2 (mod something ? No , it
's not mod , it 's exact count). However , since each square has
four edges , two red and two blue , which is equivalent to saying
that the number of red edges is even ? No , two is even , but also
, for example , if you have three red edges ...
